Cysticercosis is a frequent parasitic infection of the nervous system that occurs when humans become intermediate hosts of the pork tapeworm *Taenia solium* (*T. solium*), after ingesting its eggs. The disease is usually transmitted person-to-person, from *Taenia* carriers to healthy individuals, through non-hygienic handling of food or by direct contact with human feces. Ingestion of undercooked pork contaminated with cysticerci as the cause of human cysticercosis is a common misconception, since the role of pigs is to maintain the infection cycle by causing human taeniasis.[¹]

While cysticerci may invade the subcutaneous tissue, striated muscles and many other organs, clinically relevant disease is often observed in patients with neurocysticercosis (NCC), defined as the infection of the central nervous system and its coverings by the encysted larval stage of *T. solium*. Most symptomatic NCC patients (up to 80% of cases) develop recurrent seizures (epilepsy), which is most often seen in patients with parasites located in the brain parenchyma.[²] NCC is a major cause of secondary epilepsy in many developing countries and is currently considered the single most important disease explaining the higher number of epilepsy seen in these regions.[³] In addition, travelling and immigration of people from endemic to non-endemic areas has caused increased prevalence...
rates of epilepsy secondary to NCC in developed countries of North America and Western Europe.\textsuperscript{[6]}

For a better understanding of mechanisms involved in the pathogenesis of epilepsy secondary to NCC, a review of the stages of involution of parenchymal brain cysticerci is mandatory. After lodging in the brain parenchyma, cysticerci establish as vesicular (viable) cysts, which provoke little or no inflammatory changes in neighboring tissues. In most cases, vesicular cysts degenerate and are transformed into calcified nodules due to the attack of the host's immune system. Intermediate involutive stages during which cysticerci experience such degeneration have been called "colloidal" (cysticerci showing degenerative signs but still with liquid contents) and "granular" (compact lesions with more advanced degenerative changes) stages, respectively.\textsuperscript{[9]}

Parenchymal brain cysticerci in any of the aforementioned stages may be associated with reactive seizures. Compressive effect on the brain parenchyma is the most likely explanation for seizures occurring in patients with vesicular cysts. Degenerating cysticerci may be associated with seizures due to the inflammatory reaction induced by the host's immune attack. In cases of calcified cysticerci, the gliosis that develops around dead parasites or the exposure of remaining parasitic antigens (trapped in the interior of calcifications) to the brain parenchyma could be the cause of recurrent seizures.\textsuperscript{[6]}

Semiology of seizures related to NCC is varied. Patients with multiple parasites may present with focal seizures and those with a single lesion develop generalized seizures.\textsuperscript{[7]} The lack of anatomic-semiologic correlation between cysticerci location and seizure semiology in a sizable proportion of patients with epilepsy and NCC has long been a cause of debate and concern. This has even led to the hypothesis that both epilepsy and NCC might simply occur by chance in areas where NCC is endemic. While this is theoretically possible, MRI findings of inflammatory changes surrounding calcified cysticerci after a seizure in about 50% of cases, provides strong evidence favoring a cause-and-effect relationship between NCC and seizures.\textsuperscript{[8]}

In other cases, particularly in NCC patients with medically refractory epilepsy, chronic seizures have been shown to come from an associated atrophic or sclerotic hippocampus and not from the parasites themselves.\textsuperscript{[9]}

In these cases, the damaged hippocampus is for sure not an innocent bystander, but the result of signals or forces -- epileptogenic or inflammatory -- coming from the parasites. Most patients with hippocampal sclerosis and epilepsy -- particularly mesial temporal lobe epilepsy (MTLE) have history of perinatal trauma, recurrent febrile seizures, status epilepticus, or traumatic brain injury. Such initial precipitating injuries often lead to the development of neuronal loss in CA1 and CA3 hippocampal layers.\textsuperscript{[10]} The increasingly recognized association between granular or calcified lesions NCC lesions located within the hippocampus or in the adjacent cerebral tissue, points to this parasitic disease as the initial precipitating injury causing hippocampal atrophy and sclerosis.\textsuperscript{[11-13]} In addition, pathological reports have shown neuronal loss in the CA1 layer and gliosis, as well as the presence of a severe inflammatory reaction in the brain parenchyma surrounding calcified cysticerci.\textsuperscript{[14]} In this view, it has been postulated that calcified cysticerci could generate the development of both seizures and late hippocampal atrophy that will perpetuates the seizure disorder.

Hippocampal atrophy has also been documented in patients with calcified cysticerci located outside hippocampal areas. Different studies from Brazil and the Indian subcontinent, have revealed a significantly higher than expected prevalence of cysticercotic lesions among patients with MTLE undergoing surgery for medically intractable epilepsy.\textsuperscript{[11-19]} This, together with the finding that patients with NCC and MTLS/hippocampal sclerosis have less often history of other types of initial precipitating injuries (febrile seizures) than those with MTLS/hippocampal sclerosis alone, led to the concept that a causal relationship between NCC and MTLE with hippocampal sclerosis exists. In addition, a population-based study conducted in an Ecuadorian rural population showed a strong association between NCC and HS in community-dwelling adults.\textsuperscript{[16]} In the same population, it was demonstrated that this association is strongly related to age, suggesting that NCC-related hippocampal atrophy takes a long time to develop.\textsuperscript{[17]} Interestingly, many of the studied individuals do not had epilepsy or electroencephalography evidence of paroxysmal abnormalities, showing that the association between NCC and hippocampal atrophy may occur irrespective of seizure activity (unpublished data).

In NCC patients, the relationship between epilepsy and hippocampal atrophy/sclerosis is most likely bidirectional. According to a current hypothesis, parasite-induced inflammation is the trigger for repetitive seizures, which may cause hippocampal atrophy, which is the pathological substrate for the subsequent development of MTLE. Parasites may be located outside the hippocampal region, suggesting
a remote harmful effect of NCC-induced reactive seizures. It is also possible that cysticerci may lead to an inflammation-mediated hippocampal damage, not requiring recurrent seizures as a causative factor, as has been demonstrated in experimental studies.\textsuperscript{[18,19]}

Longitudinal studies are required to demonstrate a causal relationship between NCC and hippocampal atrophy. If this causal relationship truly exists, specific biomarkers could be identified to examine mechanisms of hippocampal epileptogenesis in humans, which have been scarcely investigated.\textsuperscript{[20]} This knowledge might allow the development of interventions directed to prevent chronic epilepsy in NCC and other forms of acquired epilepsy.
