A B S T R A C T

Oligodendrocytes are key neural cells that are responsible for producing myelin sheaths that wrap around neuronal axons in the central nervous system. Myelin is essential to insulate neurons and maintain a fast and saltatory propagation of action potentials along the axon. However, oligodendrocytes are very susceptible to damage, and thus demyelination may arise from a brain lesion or a neurodegenerative disorder. Consequently, demyelination produces a loss of axonal insulation leading to sensory or motor neuron failure. During adulthood, there are two main sources of oligodendrocytes: parenchymal oligodendrocyte precursor cells (OPCs) and subventricular zone derived OPCs. In this review, we will discuss oligodendrogenesis derived from these two sources, and also highlight their main extrinsic and intrinsic modulators. In addition, the neuroinflammatory mediators of oligodendrogenesis will also be assessed.

Key words: Demyelination, inflammation, neural stem cells, oligodendrocyte, remyelination

INTRODUCTION

Oligodendrocytes are the myelin-forming cells of the central nervous system (CNS). They are the last brain cells to be generated during development, making myelination a late event in brain maturation.[1] Their cholesterol-rich membrane loops around neuronal axons creating a myelin sheath, which is a multilamellar spiral structure that protects neurons, ensures their survival[1] and provides electrical insulation that enables faster transmission of action potentials along axons.[2] Oligodendrocytes are essential for proper brain functioning and are easily affected by oxidative stress, so that demyelination is often a secondary event to brain lesions or pathologies.[3] However, new oligodendrocytes are continuously generated during adulthood, which restore insulation of demyelinated axons and/or remodel existing myelin, an important role for functional plasticity, learning, and memory formation. This process is called remyelination, one of the few spontaneous processes of regeneration that take place in the adult CNS.[3] New oligodendrocyte production is therefore enhanced in response to a pathological insult such as demyelination. During the progression of a demyelinating disease, such as multiple sclerosis (MS), several inflammatory modulators are released by a variety of brain cells impacting the determination, proliferation, differentiation, migration, and maturation of oligodendrocyte precursor cells (OPCs), ultimately resulting in remyelination. New myelinating oligodendrocytes are derived from two main cell sources: early postnatal-derived OPCs that are present all over the brain parenchyma,[4] and new OPCs that are continuously originated from a distinct group of transit-amplifying progenitors in the subventricular zone (SVZ) of the lateral walls of the lateral ventricles.[4,5] In response to demyelination, both parenchymal OPCs and SVZ-derived OPCs produce new oligodendrocytes to recover from myelin loss.[5]

Oligodendrogenesis is a process that is regulated by extrinsic and intrinsic factors. The main external stimuli are morphogens, growth factors, and extracellular...
matrix elements while the internal stimuli important for oligodendrocyte formation are transcription factors and epigenetic regulators. Therefore, studying modulators capable of stimulating OPCs are of paramount importance and fundamental for future therapies concerning inflammatory and neurodegenerative disorders in which myelin sheaths are affected.

**OLIGODENDROGENESIS FROM OPCs DURING DEVELOPMENT AND IN THE ADULT BRAIN PARENCHYMA**

During CNS development, and also throughout adulthood, oligodendrogenesis is derived from OPCs. OPCs are a subtype of glial cell, characterized by the expression of the platelet-derived growth factor receptor α (PDGFRα), and the neuron-glial antigen 2 (NG2) proteoglycan [Figure 1].[6] Other known markers for these cells are the O4 antigen and the transcription factors Olig1, Olig2, and Nkx 2.2.[7] It should be noted that, these markers can be expressed in other cells, a combination of markers should be used to unambiguously identify OPCs.[1] In the adult brain, OPCs comprise 3-8% of the total number of cells[8] and are prevalent in the hippocampus and in all layers of the neocortex.[9]

In the developing forebrain of mice, the entire oligodendrocyte population is generated from three phases of OPC proliferation and migration. The first phase occurs at embryonic day 12.5 (E12.5) and consists of a “wave” of OPC production, originated from ventral ganglionic eminences.[10,11] At E15.5, the second phase takes place, emerging from the lateral and caudal ganglionic eminences.[12] Finally, the third phase happens after birth, with origin in the cortex.[12] These three phases are responsible for the generation of most adult oligodendrocytes in mice, which will migrate and populate most of the future brain.[1]

In human CNS development, oligodendrocyte differentiation and maturation follow similar paths to rodents.[13] This process has its beginning in the second trimester of gestation and spans into birth and adulthood.[14,15] Specifically, at 9 gestation weeks, early OPCs (NG2 and PDGFRα positive) arise from the ganglionic eminence and migrate to the cortex in the following weeks. Late OPCs, which show O4 immunoreactivity, are first detected in a small percentage at 15 gestation weeks, gaining more density in midgestation (c. 20-22 gestation weeks), especially in the subplate layer directly under the cortical plate. Finally, myelin basic protein-positive oligodendrocytes are rare at midgestation but show a steady population growth from that point on. Indeed, the first myelin sheaths can be found around 18 gestation weeks in the thalamus, spreading to the internal capsule at 21 gestation weeks.[15]

Given the nature of oligodendrocyte production, one question arises: are the OPCs involved in these different phases functionally equivalent? There is evidence that each phase of OPC production can lead to the myelination of distinct brain regions,[16] suggesting the existence of functionally different subpopulations of OPCs that serve separate functions. In fact, a study conducted in mice targeted differentially ventrally-derived OPCs (vOPCs) and dorsally-derived OPCs (dOPCs), as well as the oligodendrocytes generated by each class of OPCs (vOLs and dOLs respectively). This study shows that while vOPCs and dOPCs appear to have the same electrical properties, their migration and settling patterns are significantly different, to the point that vOLs and dOLs populate different forebrain and spinal cord regions at different timepoints during development (for example, while in adulthood the corticospinal and rubrospinal tracts are myelinated by dOLs; during early postnatal life, these regions are actually myelinated by vOLs).[16] On the other hand, it has been shown that, if one of these subpopulations is eliminated, neighboring OPCs of different origins rapidly migrate and proliferate to generate the regular number of oligodendrocytes in the mature brain,[12] which could imply that the subpopulations of OPCs are functionally equivalent.

**Figure 1:** Diagram of the oligodendrocytic lineage progression: from early oligodendrocyte precursor cell to functioning mature myelinating oligodendrocyte.
After CNS development, a small fraction of OPCs remains undifferentiated, in an immature slowly proliferative or quiescent state. These adult OPCs are morphologically equivalent and express the same markers as the OPCs present during development. However, they differ from the developing OPCs in growth factor responsiveness, migration capacity, and cell cycle length. Their cell density, although stable throughout adult life, is higher in white matter than in gray matter. Indeed, it has been shown that adult OPCs present a higher rate of proliferation in white matter, which is a possible explanation for the difference in cell density. It is possible to further divide white matter OPCs and gray matter OPCs by their characteristics. While white matter OPCs are proliferative and eventually lead to adult oligodendrogenesis, gray matter OPCs remain quiescent and immature.

Given these findings, could adult OPCs be a heterogeneous population, possibly with several distinct functions? Some studies show that the different characteristics observed in adult OPCs can be the result of environmental signals. Specifically, gray matter environment is described as an inhibitor of OPC proliferation and differentiation while white matter environment seems to favor OPC maturation. These differences may be linked to intrinsic cell mechanisms or to environmental cues. While there seem to be differences in the local microenvironment surrounding OPCs in white and gray matter, the different characteristics of white matter and gray matter OPCs can also be explained by intrinsic mechanisms, such as receptor desensitization. For instance, it is known that, in the developing spinal cord, PDGF-A mRNA has higher expression in the gray matter, which can lead to desensitization of the receptor (PDGFRα) and prolonged impairment of gray matter OPCs maturation. However, there are indeed molecular differences between white matter OPCs and gray matter OPCs, namely in the resting membrane potential and ion channels expression. Concerning the ion channels, two subpopulations of adult OPCs have been described: one completely devoid of voltage-gated Na+ channels, and another with functional channels, able to react to action potentials. Consequently, this second subtype can sense neuronal activity through axonal input and is more sensitive to ischemia. Another study corroborating the existence of functionally different subtypes shows that white matter OPCs can generate myelinating oligodendrocytes even if they are transplanted into other brain regions. Gray matter OPCs, in contrast, remain less efficient even if transplanted into white matter. Therefore, it seems that white matter OPCs are more prepared to generate new myelinating oligodendrocytes than gray matter OPCs. What is the role of OPCs in gray matter remains a question to be explored.

In response to a demyelinating insult, the remyelination process is activated. New myelinating oligodendrocytes are mainly generated from early postnatal-derived OPCs that are present in the brain parenchyma. In a first phase, quiescent or slow-dividing OPCs are recruited to the damaged areas OPCs start to proliferate, migrate, and populate the demyelinated area. In a second phase, the recruited OPCs start to differentiate into mature oligodendrocytes as they form myelin sheaths around demyelinated axons. Oligodendrocytes derived from parenchymal OPCs are only able to migrate short distances, just populating damaged areas in the proximity of their progenitor cells.

**OLIGODENDROGENESIS DERIVED FROM ADULT SUBVENTRICULAR ZONE NEURAL STEM CELLS**

After birth, OPCs can be produced by adult neural stem cells (NSC), which are self-renewing, multipotent cells that generate most of the cells of the nervous system, such as neurons, astrocytes, and oligodendrocytes. These NSCs can divide in three different ways: symmetrically, originating in two new NSCs (expansion, symmetrical self-renewal); asymmetrically, originating one NSC and one differentiated cell (maintenance, asymmetrical self-renewal); or symmetrically, originating two differentiated cells (extinction, symmetrical commitment). Depending on the activation of specific signaling pathways and the presence of differentiation-inducing molecules, NSCs are capable of differentiating into cells of neuronal (neurogenesis) and glial (gliogenesis) lineages, particularly oligodendrocytes (oligodendrogenesis).

Neural stem cells exist in discrete regions of the adult mammalian brain where neurogenesis and oligodendrogenesis are highly regulated. The brain regions where these processes take place, that is where the NSC pools can be encountered, are called neurogenic niches. In adulthood, there are two main neurogenic niches in the brain: the SVZ of the lateral ventricles, and the subgranular zone of the dentate gyrus (DG) of the hippocampus. In the SVZ, the NSC pool comprises type B cells, which are quiescent NSCs that originate type C cells, which are fast dividing transient amplifying cells. Most of these C cells will then differentiate into neuroblasts (type A cells), migrate along the rostral migratory stream to the olfactory bulb, and terminally differentiate into interneurons. SVZ-derived oligodendrogenesis originates from a minority of C cells that do not follow the previously explained cellular fate. Instead, they
produce OPCs, which migrate radially out of the SVZ into the surrounding cortex and white matter [Figure 2].\(^5,38,39\)

It should be noted that one NSC can generate either oligodendrocytes or neurons exclusively\(^{[33]}\) and that the number of oligodendrocytes produced by the SVZ NSC pool is significantly inferior to the number of olfactory interneurons.\(^{[9]}\) The relative quantity of oligodendrocytes and neurons is area dependent: while in the posterior zone of the SVZ, the ratio is one oligodendrocyte to three neurons; in the rostral zone, this ratio is 1:30.\(^{[5]}\) The ratio also changes dorsoventrally, due to environmental cues. The dorsal part of the SVZ is Wnt enriched, which favors OPC commitment.\(^{[13]}\)

On the other hand, the ventral part is more exposed to bone morphogenic proteins (BMP), which inhibits OPC specification.\(^{[40]}\)

Contrary to the parenchymal OPCs, SVZ-derived OPCs, although a minority in the brain, can migrate long distances into the corpus callosum, striatum, and fimbria fornix, where they continue to divide or differentiate into mature myelinating and nonmyelinating oligodendrocytes.\(^{[5]}\) Adult SVZ progenitor cells mostly generate neuronal lineage cells and only a few oligodendrocytes; however, progenitor cells show some lineage plasticity in pathological conditions. In a demyelination context, OPC production in SVZ is favored to the detriment of neuronal precursor cells. These OPCs then migrate to the affected areas, where they differentiate into oligodendrocytes, contributing to the remyelination process [Figure 3].\(^{[4,5,41,42]}\)

The generation of new oligodendrocytes from the SVZ is possible because adult NSCs, from which OPCs are derived, are embedded in the specialized and diverse microenvironments of the SVZ niche, which is responsible for regulating NSCs and their progenies’ self-renewal and differentiation by receiving information from the brain and other tissues.\(^{[43–45]}\)

The first specialized microenvironment is the apical ependymal compartment where slow-dividing type B cells are in direct contact with the cerebrospinal fluid (CSF) present in the space of the lateral ventricles, through a specialized apical process surrounded by ependymal cells.\(^{[43–44,46]}\) The adult choroid plexus (CP) expresses and secretes to the CSF not only numerous trophic factors but also cytokines, which can influence the behavior of SVZ progenitor cells, modulating the self-renewal capacity, proliferation, and differentiation [Figure 2].\(^{[43,44]}\) Interleukin-1β (IL-1β) is one of the cytokines that are secreted and regulated by CP, which acts on type B cells through binding to IL-1 receptors to up-regulate vascular cell adhesion molecule 1 expression, modulating type B cells adherence to the SVZ niche. Insulin-like growth factor 2 (IGF-2) is also present in the adult CSF and regulates SVZ progenitor proliferation.\(^{[44]}\) Moreover, CP also secretes guidance molecules, such as chemorepulsive factors and chemoattractants, which regulate SVZ NSCs and their progenies’ migration.\(^{[42]}\) CP changes its secretome under pathological conditions, leading to a different CSF cellular and molecular composition that will then influence the SVZ niche population. For example, during peripheral tissue inflammation, inflammatory information from the blood can have an impact in the CNS.\(^{[47,48]}\) Peripheral inflammation elicits the up-regulation of cytokines, adhesion factors, and signaling pathway genes, such as tumor necrosis factor-α (TNF-α), IL-1β, and small inducible cytokine A2 transcripts that are under the regulation of the NF-κB cascade, in the CP.\(^{[47]}\) Then the CP, through changes in CSF composition, will affect the SVZ niche population.

The second SVZ niche component is the basal vasculature, composed of blood vessels and a basal lamina rich in laminin.\(^{[42]}\) Here, type B cells have a long specialized basal process through which they interact with blood vessels, and fast-dividing/transit-amplifying type C cells are also in very close proximity to blood vessels.\(^{[43–46]}\) Endothelial cells secrete several diffusible signals, such as fibroblast growth factor-2 (FGF2),
IGF-1, brain-derived neurotrophic factor (BDNF), chemokines, among others, which also influence stem cell self-renewal, proliferation, and fate determination in the SVZ [Figure 2].[44-46,49] In addition, cerebral endothelial cells promote differentiation of SVZ NSCs into oligodendrocytes, being important for the proliferation and migration of OPCs.[42]

The extracellular matrix composition of the vascular basal lamina makes the basal lamina an important integration site for the exchange of signals between the SVZ progenitors and the main compartments of the SVZ niche, the vasculature and the CSF, because it provides, stores, and compartmentalizes growth factors and cytokines.[42,45]
By changing the composition of CSF or the blood stream, it would be possible to modulate proliferation and or differentiation of SVZ progenitors with an impact on demyelinating diseases; however, these modifications should be tightly regulated to maintain brain homeostasis.

MODULATORS OF OLIGODENDROGENESIS

Extrinsic factors

The extrinsic factors include morphogens, growth factors, and signaling molecules delivered through blood vessels or associated with the extracellular matrix. For instance, during the development of both the brain and spinal cord, the relative levels of Sonic hedgehog (Shh), BMP, and Wnt/β-catenin have been shown to play roles in oligodendrocyte determination. The motoneuron domain (pMN) is a restricted domain of the ventral ventricular zone of the embryonic spinal cord, and in mice, cells in this domain express the transcription factors Olig1 and Olig2.[50] In this zone, Olig2 expression is crucial for the production of motoneurons and oligodendrocytes. In order for this transcription factor to induce oligodendrogenic cell fate instead of neuronal differentiation, a switch must occur.[11] As seen in both mice and zebrafish, this switch is highly dependent on the level of Shh in the environment[51] and on the Notch/delta pathway, which restricts the production of motoneurons, thus allowing oligodendrocyte determination.[52] On the other hand, this switch is repressed if high level of BMPs and Wnt are locally present.[53] It has also been shown that, during brain development, Shh promotes the generation of ventrally derived OPCs,[11] while Wnt/β-catenin and BMPs inhibit it. Curiously, in the adult brain, there is an apparent contradiction since Wnt3 (from the Wnt family) promotes oligodendrocyte specification in the SVZ.[13]

Other extrinsic factors modulate oligodendrogenesis in the adult SVZ. Evidence shows that both factors secreted by blood vessels and factors connected to the extracellular matrix are capable of favoring OPC commitment.[13,54,55] One of these factors is laminin, an element of the extracellular matrix. A study in mice shows that the elimination of laminin α2-subunit leads to a reduction of the OPC population in the SVZ.[56] Other trophic factors, such as PDGF,[57,58] and epidermal growth factor (EGF),[59,60] contribute indirectly to oligodendrocyte lineage determination, through promoting OPC proliferation and maturation. Additionally, IGF-1 also contributes to oligodendrogenesis by blocking BMP signaling, both in vivo and in vitro [Table 1].[61]

Intrinsic factors

The intrinsic factors that modulate oligodendrogenesis include transcription factors and epigenetic regulators. The main transcription factor involved in oligodendrogenesis is Olig2. This basic helix-loop-helix (bHLH) factor is induced by Shh[76] and expressed in every stage of oligodendrocyte maturation, from OPC to myelinating oligodendrocyte.[1] In the majority of the CNS, inactivation of Olig2 during development leads to a reduction in OPCs.[76-78] In contrast, overexpression of Olig2 in neuroepithelium leads to enhanced OPC production in the CNS.[79] Furthermore, the presence of Olig2 is sufficient to reprogram rat and mouse fibroblasts into induced OPCs.[80,81] Although this factor is crucial to oligodendrocyte differentiation, Olig2 knockout mice are still able to produce some OPCs in the hindbrain, possibly through Olig1 compensation.[76]

Another important transcription factor is Achaete-scute homolog 1 (Ascl1 or Mash1), which is also a bHLH factor.[1] During development, absence of Ascl1 leads to a reduction of OPC production in the brain and spinal cord.[82,83] However, this reduction can be compensated to normal values by Ascl2 and 3.[83] After birth, Ascl1 is only expressed in C cells and OPCs in the SVZ[80] and similarly to what happens during CNS development, elimination of this transcription factor leads to decreased OPC generation.[80]

NSC: neural stem cell; OPC: oligodendrocyte precursor cell; pMN: progenitors of motor neurons; Shh: sonic hedgehog; BMP: bone morphogenic protein; EGF: epidermal growth factor; FGF-2: fibroblast growth factor-2; IGF-1: insulin-like growth factor-1; PDGF: platelet-derived growth factor; ASCL1: achaete-scute homolog 1
The Nkx and Sox families also play roles in oligodendrogenesis, even though they are not critical.\textsuperscript{[84]} Ablation of Nkx6.1/Nkx6.2 blocks the production of both oligodendrocytes and motoneurons in the pMN.\textsuperscript{[79,80]} Additionally, Sox9 knockout mice show deficits in glial specification, presenting a reduced number of oligodendrocytes and astrocytes.\textsuperscript{[72]} Furthermore, if there is a Sox8/Sox9 double inactivation, no oligodendrocytes are produced, which suggest that Sox8 and Sox9 serve redundant functions in relation to oligodendrogenesis.\textsuperscript{[72]}

In the last few years, epigenetic modulation of oligodendrogenesis has been gaining some importance, namely regarding the modulation by microRNA and histone modifications. One of the most described microRNA in oligodendrogenesis is miRNA-7a. This miRNA is highly enriched in OPCs and overexpressing it in neuronal progenitors during brain development promotes OPC commitment, both \textit{in vivo} and \textit{in vitro}.\textsuperscript{[73]} In contrast, blocking miRNA-7a function inhibits OPC generation and favors neuronal progenitors.\textsuperscript{[73]}

Histone modifications can also be important for oligodendrogenesis. For instance, it has been shown that oligodendrocyte production from NSCs, instead of other cellular fates, depends on histone deacetylases (Hdac) activity.\textsuperscript{[85]} Similarly, a study using Enhancer of zeste homolog 2 (Ezh2), a polycomb group protein involved in gene silencing through histone methylation, provided evidence that a higher rate of histone methylation (via Ezh2 overexpression) leads to an increase in oligodendrocyte production [Table 1].\textsuperscript{[74]}

**IMMUNE MEDIATORS OF OLIGODENDROGENESIS**

When white matter is damaged as a result of an infection, a trauma or a neurodegenerative disease such as MS or vascular dementia, microglia, the brain’s innate immune cells, are activated. Microglia removes infectious agents and apoptotic cells, through phagocytosis and by producing reactive oxygen species (ROS), TNF-\(\alpha\), nitric oxide (NO), IL-1\(\beta\), and prostaglandin E2.\textsuperscript{[86]} When microglia are chronically activated, sustained release of inflammatory factors, cytokines, and chemokines compromises the blood-brain barrier (BBB), resulting in vascular permeability to blood and circulating immune cells, such as T and B lymphocytes and macrophages, as well as recruitment of these peripheral immune cells to the lesion site.\textsuperscript{[87]} By recognizing their specific autoantigen presented by MHC class II molecules on the surface of antigen presenting cells, CD4\(^+\) T cells are activated and attack the myelin sheath.\textsuperscript{[87]} Antigens on MHC class I molecules also activate CD8\(^+\) T cells to attack myelin, demyelinated axons, and dying motoneurons through the activation of the perforin pathway, the delivery of granzymes into the cells, or by Fas-Fas ligand interactions.\textsuperscript{[86]} Additionally, B lymphocytes produce autoantibodies against myelin antigens, degrading myelin sheath. Because infiltrating effector T cells, microglia and macrophages release cytokines and chemokines, inflammation will be exacerbated and consequently more T cells, B cells, and innate immune cells will be recruited to the lesion site, contributing to chronic neuroinflammation, and neurodegeneration [Figure 3].\textsuperscript{[87]}

Neuroinflammatory responses can be deleterious for cell survival, resulting in irreversible extensive damage to the brain, especially if they are prolonged in time.\textsuperscript{[86]} However, they have also been described as having beneficial effects and as being critical for the activation of the brain repair process, such as for the remyelination program. As a result of white matter damage, there is an accumulation of apoptotic cells and myelin debris in the lesion site, which have been demonstrated to be inhibitory to axonal regeneration, as well as affecting OPC differentiation into mature myelinating oligodendrocytes. However, through phagocytosis of cellular debris and apoptotic cells, microglia and brain infiltrating macrophages function toward repairing the damaged tissue, by promoting a pro-regenerative environment, promoting OPC recruitment and differentiation, thus favoring remyelination and axon regeneration.\textsuperscript{[29,89-91]} For instance, ROS hydrogen peroxide (H\(_2\)O\(_2\)), released by macrophages and microglia, destroys damaged cells, affecting not only healthy surrounding cells, but also promoting proliferation and differentiation of NSCs into oligodendrocytes.\textsuperscript{[92]} Astrocytes have also been described to have an important, yet controversial, role in demyelinating diseases. Astrocytes have been shown to have an important role in both demyelination and remyelination.\textsuperscript{[93-95]} On the one hand, because astrocytes are antigen-presenting cells and release cytokines and chemokines, they contribute to myelin damage through an immune-mediated demyelination by recruiting inflammatory cells, such as T lymphocytes, microglia, and macrophages to the lesion site.\textsuperscript{[93]} On the other hand, astrocytes are described as being responsible for a successful remyelination through the regulation of the clearance of myelin debris\textsuperscript{[94]} and oligodendrogenesis in the lesion site [Table 2].\textsuperscript{[93]} Astrocytes promote OPC migration, proliferation, and differentiation after demyelination by secreting several factors, which have an impact on myelin repair.\textsuperscript{[93]} In fact, several cytokines and chemokines produced by microglia, macrophages, and astrocytes in response to brain injury have been described as having an essential
With the progression of the demyelinating disease, or even with ageing, there is an impairment of the remyelination process due to a decrease of pro-oligodendrogenic signals and an increase of anti-oligodendrogenic signals from immune cells that compromises oligodendrocyte maturation and myelination, leading to high inflammation and cell death.\(^{[42,106,112]}\)

There are still contradictory actions of immune mediators that need to be clarified. The use of limited models of demyelination can be a cause for some of those differences. Thus, it is necessary to develop combined models that will help us to better understand the mechanisms of demyelination and remyelination. How cell immune mediators can be either beneficial or detrimental to the remyelination process and how these responses can change with aging are key questions to successfully develop remyelinating or neuroprotective therapeutic strategies.

**CONCLUSION**

In the CNS, myelin is produced and maintained by oligodendrocytes. Therefore, new treatments to overcome demyelinating disorders could be primed by targeting this type of cell. In fact, in a demyelinating disorder, parenchymal OPCs spontaneously remyelinate newly nude axons in damaged areas. Moreover, NSCs can be a source of new oligodendrocytes for use in regenerative medicine concerning myelin pathologies. In this review, we have highlighted some of the key players of oligodendrogenesis and that may be used in the future for therapies concerning demyelinating disorders [Figure 4].
