Key words: Artery of Percheron; bilateral thalamic infarcts; coma; diffusion-weighted imaging; thalamic dementia

ABSTRACT

Bilateral thalamic infarcts have a low frequency among different subtypes of strokes. Since it does not involve a particular vascular territory, it therefore usually involves the occlusion of the artery of Percheron (AOP). Here we report a 79-year-old right-handed Parkinsonian female patient, who was found unresponsive in bed. On examination, the patient was drowsy with a Glasgow Coma Score (GCS) of 10/15 (E2M5V3). She had absent doll’s eye response with anisocoric pupils and intermittent vertical gaze palsy. Although the patient had no apparent motor deficits, she was in a state of persistent somnolence with memory impairment and lack of initiative. Diffusion-weighted magnetic resonance imaging (MRI) of the brain showed focal areas of restricted diffusion in the medial part of the thalami bilaterally and the rostral part of mid-brain (right > left) (bilateral paramedian thalamic with mid-brain pattern), suggestive of a hyper-acute infarct in the territory of AOP. The patient was anticoagulated with 40 mg subcutaneous low molecular weight heparin and was started on double anti-platelets along with supportive measures. The level of consciousness is improved at a slow rate to a GCS of 12/15 (E2M5V3). The patient had marked abulia with periods of drowsiness interspersed with periods of restlesslessness and uttering of abnormal sounds, but she was able to execute simple commands. In conclusion, occlusion of the AOP is a rare cause of coma in elderly patients. Diffusion-weighted MRI is the imaging modality of choice for early diagnosis. Early diagnosis of AOP occlusion may lead to favorable outcomes.

INTRODUCTION

Bilateral thalamic infarcts have a low frequency among different subtypes of strokes. These infarcts involve the medial aspects of the thalamus in a relatively symmetrical pattern with or without simultaneous involvement of the rostral mid-brain bilaterally. Since it does not involve any of the particular vascular territories, this usually points out to the occlusion of the artery of Percheron (AOP).[1] AOP is a solitary arterial trunk which arises from one of the proximal segments of the posterior cerebral artery and supplies the thalamus and certain structures of the rostral midbrain. The low sensitivity of computed tomography (CT) makes AOP infarction diagnosis difficult. Diffusion-weighted magnetic resonance imaging (MRI) is the imaging modality of choice.[1] However, AOP is rarely visualized on magnetic resonance angiography, and lack of visualization does not exclude its presence.[²] The incidence of AOP occlusion is rare, and early diagnosis

is challenging. It varies 0.1-2% in all ischemic strokes and 4-18% in thalamic infarction.[2] Here, we report a case of bilateral thalamic infarct due to occlusion of the AOP.

CASE REPORT

A 79-year-old right-handed Parkinsonian female was found unresponsive in her bed at home. She was last seen normal approximately 8 h prior to her admission. There was no recent history of fever, headache, seizure, trauma, and known exposure to toxic substances. There was no history of any memory impairment or dementia. On examination, the patient was drowsy with a Glasgow Coma Score (GCS) of 10/15 (E2M5V3). She had absent doll’s eye response with anisocoric pupils and intermittent vertical gaze palsy. The deep tendon reflexes were present and symmetric. Babinski sign was present bilaterally. Although the patient had no apparent motor deficits, she was in a state of persistent somnolence with memory impairment and lack of initiative.

Investigations

Laboratory findings including blood glucose, complete blood count, serum electrolytes, liver and renal function tests, thyroid function tests, arterial blood gas, and ammonia were unremarkable. Electrocardiogram showed normal sinus rhythm.

Imaging

The initial CT showed no obvious brain lesion. MRI of the brain showed focal areas of restricted diffusion [Figures 1 and 2] in the medial part of the thalami bilaterally (bilateral paramedian thalamic with mid-brain pattern), and in the rostral part of mid-brain (right > left). Echo-planar two-dimensional perfusion imaging revealed areas of decreased perfusion in the areas of restricted diffusion [Figure 3]. There were V-shaped hyper-intense signal areas in the pial surface of the midbrain adjacent to the interpeduncular fossa, and therefore, no abnormal signs in this region on the T2-weighted scan [Figure 4]. These imaging findings were suggestive of a hyper-acute infarct. MRI data demonstrated patent basilar tip and posterior cerebral arteries [Figure 5]. Hence, the possibility of hyper-acute infarct in the territory of AOP was considered.

Treatment

The patient was anticoagulated with 40 mg subcutaneous low molecular weight heparin. The level of consciousness is improved to a GCS of 12/15 (E4M5V3). The patient had marked abulia with periods of drowsiness interspersed with periods of restlessness and uttering of abnormal sounds, but she was able to execute simple commands. The patient is currently under our follow-up. She is on anticoagulation. Her consciousness is gradually improved. However, her memory impairment was still persisting as her mini mental state examination score was 23 of 30.

DISCUSSION

Our case illustrates the importance of considering ischemic stroke in the AOP territory as one of the differential diagnosis of acute disturbance of consciousness in the elderly. Bithalamic paramedian infarcts due to occlusion of AOP presents with vertical gaze palsy (65%), memory...
impairment (58%), confusion (53%), and coma (42%). Vertical gaze palsy is due to the disruption of the cortical input that traverses the thalamus to reach the rostral interstitial medial longitudinal fasciculus. Memory impairment, confusion, and coma classically seen in bilateral thalamic infarction, often called together as “thalamic dementia” is explained by the involvement of the reticular activating system and the disrupted connections between the thalamus and the cortex. Thalamic dementia does not develop in case of unilateral lesions.

These patients must be differentiated from those with “top of the basilar artery” syndrome and deep cerebral venous thrombosis (DCVT). “Top of the basilar artery” syndrome tends to involve the superior cerebellar artery and posterior cerebral artery territories. MRI showing patent basilar tip and posterior cerebral arteries exclude this diagnosis in our patient. MRI pattern does not confine to a typical arterial territory in DCVT.

Percheron described four normal variations of the neurovascular anatomy of the thalamus and the midbrain. The medial part of the thalamus is supplied from the posterior circulation via the perforating thalamic arteries, which are also known as the paramedian arteries. Occlusion of AOP causes a bilateral paramedian thalamic and rostral midbrain infarction. Most of the AOP infarction is due to small vessel occlusion or cardiac embolism.

Successful tissue plasminogen activator therapy for AOP occlusion is reported in literature, but our patient was outside the treatment time window on the initial presentation. Long-term anticoagulant therapy is the current treatment strategy suggested for AOP occlusion.

In comparison to ischemic lesions of other cortical-subcortical structures, thalamic stroke has a lower mortality rate and a better prognosis as far as the recovery of motor deficits is concerned. On the contrary, the neuropsychological deficits in terms of memory, cognition, emotional response and behavior tend to persist, and interfere with the social and professional life of the patient.

In conclusion, occlusion of the AOP is a rare cause of coma in elderly patients. Diffusion-weighted MRI is the imaging modality of choice for early diagnosis. Early diagnosis of AOP occlusion may lead to favorable outcomes.
